**Abstract.** The effects of mutations of the gene for tyrosinase-related protein 1 (TYRP1) on the black muscles and coat color in Nanping black-boned sheep were investigated. Tyrosinase activity and melanin content in plasma were measured and compared in three random groups of sheep: Nanping black-boned (101 heads), Nanping normal (106 heads) and Romney Marsh sheep (82 heads, *Ovis aries*). Eight exons and their partial flanking regions of the *TYRP1* gene were amplified. Six intronic mutations and six exonic polymorphisms including two non-synonymous mutations [c.203C > T (p.A68V) and c.1202T > C (p.V401A)] were identified. Using a bi-directional polymerase chain reaction allele-specific amplification (bi-PASA) of the mutation c.203C > T it was shown that the frequencies of allele C in the Nanping black-boned, Nanping normal and Romney Marsh sheep were respectively 0.955, 0.967 and 0.744. For the mutation c.1202T > C, the frequencies of allele T in the three populations of sheep were respectively 0.777, 0.745 and 0.793 as measured using the single-strand conformation polymorphism. When the data from sheep of all three populations with the CC genotype of SNP c.203C > T were pooled, it was found that there was significantly higher ( $P < 0.05$ ) tyrosinase activity, content of alkali-soluble melanin and ratio of eumelanin : total melanin than in the plasma of sheep with the CT and TT genotypes. This was not so within each of the three groups of sheep. No significant effect of the *TYRP1* genotype on coat color was found. Further studies will be necessary to determine the cause of the black traits in Nanping black-boned sheep.

## 1 Introduction

The black-brown pigment eumelanin and a related reddish-yellow pigment, pheomelanin, are found naturally in the tissues of both invertebrates and vertebrates (Ito and Wakamatsu, 2008; Dubey and Roulin, 2008). The integument color in mammals is mostly determined by the ratio and quantities of these two pigments. These pigments are synthesized in cutaneous melanocytes and transported to surrounding epidermal keratinocytes (Vachtenheim and Borovanský, 2010; de Araújo Lima et al., 2015). L-tyrosine to dopamine conversion in the synthesis of melanin within melanocytes

is catalyzed by the tyrosinase (EC1.14.18.1) (Hall and Orlow, 2005). Other factors and enzymes also regulate the amount and quality of the melanin synthesized (Bellei et al., 2011; Aydin et al., 2012). Furthermore, sheep melanocytes (melanogenesis) will spontaneously lose their partial function during a period of weeks to months after birth (Aliev et al., 1987).

Tyrosinase-related protein 1 (TYRP1), encoded by the *TYRP1* gene, catalyzes the oxidation of 5,6-dihydroxyindole-2-carboxylic acid (DHICA) to indole-5,6-quinone-2-carboxylic acid at a point within the pathway for the synthesis of eumelanin (Toyoda et al., 2004). The activity

of tyrosinase is increased by *TYRP1* stabilizing its structure (Manga et al., 2000; Slominski et al., 2004). The *TYRP1* gene has been cloned and there are numerous reports on the effects of mutations of the gene on skin and coat color in mammals, including humans (Sturm et al., 1995; Rooryck et al., 2006), mice (Zdarsky et al., 1990), goats (Becker et al., 2015), sheep (Gratten et al., 2007, 2008), cattle (Berryere et al., 2003; Guibert et al., 2004), pigs (Okumura et al., 2005, 2008), horses (Rieder et al., 2001), cats (Schmidt-Kuntzel et al., 2005; Lyons et al., 2005), dogs (Schmutz et al., 2002) and rabbits (Utzeri et al., 2014) as well as non-mammalian species including chickens (April et al., 1998) and quail (Nadeau et al., 2007; Xu et al., 2013). Moreover, it has been highly expressed in black skin (Fan et al., 2013).

We have reported the identification of black-boned sheep (*Ovis aries*) within a population of Nanping indigenous sheep. These black-boned sheep have dark-colored (black) tissues compared to the reddish coloration of the tissues of the normal sheep in the flock (Deng et al., 2006). The trait for the dark coloration has been shown to be inherited in cross-breeding studies (Deng et al., 2008) and the Nanping black-boned sheep have been recognized as a novel genetic resource by the Chinese Ministry of Agriculture.

In the present study we cloned the eight exons of the ovine *TYRP1* gene with a view to identifying potential polymorphisms and to determining whether polymorphisms of the gene might explain the black traits and coat color of the Nanping black-boned sheep.

## 2 Materials and methods

All experiments performed in this study were approved by the International Animal Care and Use Committee of the Yunnan Agricultural University. The care and use of animals fully complied with local animal welfare laws, guidelines and policies.

## 3 Sheep and collection of blood

Three groups of sheep (*Ovis aries*) were used for the study. Two groups of sheep more than 1 year of age were identified in a flock of indigenous sheep in Nanping County, Yunnan Province, PRC. A group of 101 were classified as Nanping black-boned (NPBB) sheep and a second group of 106 were classified as Nanping normal (NPN) sheep. A third group of 82 mature Romney Marsh (RM) sheep were kept at the Yunnan Malong Sheep Stud Farm, Malong County, Yunnan Province, PRC. All sheep grazed on pasture consisting of natural grasses and herbs during the day and were penned at night.

A blood sample was collected from each sheep in the morning prior to releasing the sheep to pasture. The blood was collected from the external jugular vein by direct venipuncture, and each sample was distributed to six aliquots

into sterile tubes. Sodium citrate was added to six of the aliquots prior to centrifugation to obtain plasma. All three tubes of blood or plasma were then snap frozen in liquid nitrogen before storing at  $-80^{\circ}\text{C}$  pending analyses.

At the time of collection of blood the wool color of each sheep was recorded as either black, white mixed (black, brown and white) or brown.

## 4 Isolation of exons and identification of DNA polymorphisms

Whole blood samples from five sheep chosen randomly from each of the NPBB, NPN and RM groups were used for the identification of polymorphisms. Genomic DNA was extracted from each blood sample using a TIA Namp Blood Kit (Tiangen Biotech Co. Ltd., Beijing, China). The reference genomic sequence was obtained from the sheep (EF102110) *TYRP1* gene complete coding region, which has been posted on COW BLAT Search (<http://genome.ucsc.edu/cgi-bin/hgBlat>).

Primers were designed in inferential introns using primer Premium 5.0 software to provide optimal polymerase chain reaction (PCR) products. Eight primers were designed to amplify each exon and its partial flanking region of the *TYRP1* gene (Table 1). The PCR mixture contained 2  $\mu\text{L}$  (20–50 ng) of genomic DNA, 1.5  $\mu\text{L}$  of 25 mM  $\text{MgCl}_2$ , 1.0  $\mu\text{L}$  of 10 pmol  $\mu\text{L}^{-1}$  forward primer, 1.0  $\mu\text{L}$  of 10 pmol  $\mu\text{L}^{-1}$  reverse primer, 0.5  $\mu\text{L}$  of 10 pmol  $\mu\text{L}^{-1}$  dNTP (deoxy-ribonucleoside triphosphate) mixture, 0.4  $\mu\text{L}$  of 5 U Taq polymerase and 2.5  $\mu\text{L}$  of 10  $\times$  PCR buffer at a final volume of 25  $\mu\text{L}$ . Each PCR reaction was performed in a Gene Thermal Cycle (Hangzhou, China) using the protocol shown in Table 1. The PCR program started with denaturation at  $94^{\circ}\text{C}$  for 3 min, followed by 38 cycles of  $94^{\circ}\text{C}$  for 45 s, Ta (annealing temperature) for 45 s,  $72^{\circ}\text{C}$  for 60 s then an extended  $72^{\circ}\text{C}$  cycle for 5 min and finally  $4^{\circ}\text{C}$  to terminate the reaction. The PCR products were sequenced bi-directionally using an ABI 3730 DNA analyzer (Applied Biosystems Inc.) at the Sun Biotechnology Company (Beijing, China).

## 5 Genotyping

All collected samples except those sequenced previously were genotyped as follows.

Due to the lack of a suitable restriction nuclease for the single nucleotide polymorphism (SNP) g.203C > T, a bi-directional PCR allele-specific amplification (bi-PASA) system was designed to quickly and conveniently detect the genotype of SNP g.203C > T. The Bi-PASA method, based on a one-tube reaction, permits a distinction to be made between the different genotypes by using two outside primers and two inner (allele-specific) primers at the mutation point (Liu et al., 1997).

**Table 1.** Primers and PCR conditions.

Primer	Primer sequence (5'–3')	Target	Amplicons (bp)	Ta (°C)
TYRP1-exon 1	F: CAGACAGAAAACCCACAAG R: CCAACCCACCTTCAAAATGCTT	Exon 1 and flanking regions	487	51
TYRP1-exon 2	F: GCATTTTGAAGGTGGGTTGG R: ACCTCAACTGATTCAAAGGTCTG	Exon 2 and flanking regions	635	57
TYRP1-exon 3	F: TGGGGTTACAAGATGATTGAG R: TTTGGCTTCCTGACCATTTGAT	Exon 3 and flanking regions	639	54

SSCP-exon 6	F: CCTTCACAATTTGGCTCATCTATTCCT R: GAAACAGTCTCACCAGCATTGTATCG	c.1202T > C	150	55

The bi-PASA PCR reactions were performed in a mixture (25  $\mu$ L) containing 2  $\mu$ L of genomic DNA, 1  $\mu$ L of 25 mM MgCl<sub>2</sub>, 0.25  $\mu$ L of 10 mM outside primer, 0.5  $\mu$ L of 10 mM inner primer (Table 1), 0.5  $\mu$ L of 20 mM dNTP mixture, 0.2  $\mu$ L of 5 U Taq polymerase, 3  $\mu$ L of 10  $\times$  buffer and 16.8  $\mu$ L of water. The thermal cycling PCR conditions were 94 °C for 3 min, 40 cycles at 94 °C each for 45 s, 60 °C for 45 s and 72 °C for 45 s with a final extension at 72 °C lasting for 5 min. Following the PCR an aliquot of 20  $\mu$ L of the PCR bi-PASA product was separated on agarose gel (1.5 %, w : v), which was finally stained with ethidium bromide to permit visualization.

The single-strand conformation polymorphism (SSCP) method was used to identify SNP g.1202T > C by using another primer (SSCP-exon 6); see Table 1. The PCR mixtures contained 0.75  $\mu$ L of 10 pmol  $\mu$ L<sup>-1</sup> forward primer and 0.75  $\mu$ L of 10 pmol  $\mu$ L<sup>-1</sup> reverse primer with the remainder of the mixture as outlined above for the bi-PASA reactions. Aliquots of 2  $\mu$ L of the PCR products were mixed with 5  $\mu$ L of denaturing solution containing 98 % (w : v), deionized formamide, 0.01 mM EDTA, 0.25 % (w : v) xylene cyanol, 0.25 % (w : v) bromophenol blue and 2 % (w : v) glycerol; these were heated for 10 min at 98 °C and then chilled

immediately on ice. Denatured DNA was subjected to electrophoresis on polyacrylamide gel (14 %, w : v) in 1  $\times$  TBE buffer at a constant voltage of 200 V overnight at 4 °C. Thereafter the gels were stained with 0.36 % (w : v) silver nitrate.

## 6 Measurement of melanin-related traits

The method described by Pomerantz (1963) was used to measure the activity of tyrosinase in plasma. Briefly, L-dopamine was used as a substrate to measure the activity of the enzyme with a spectrophotometer set at a wavelength of 475 nm. One unit of enzyme was defined as the amount causing the uptake of 1  $\mu$ L of O<sub>2</sub> per minute in a total volume of 3 mL including 1 mg of dopa, 0.1 M sodium phosphate buffer, a pH of 6.8 and a constant temperature of 37 °C.

The concentration of plasma pheomelanin (SpPM) was measured using a spectrophotometric assay (Ozeki et al., 1995, 1996a). An aliquot of 200  $\mu$ L of each plasma sample was added to 800  $\mu$ L of phosphate buffer with pH 10.5. The mixture was agitated vigorously for 10 min at room temperature then the mixture was centrifuged at 10 000 rpm for 10 min before 1 mL of chloroform was added to the supernatant to remove fatty impurities. The pale yellow aqueous

layer containing phaeomelanin was cleared by centrifugation at 10 000 rpm for 10 min and the absorbance was measured at 400 nm ( $A_{400}$ ). Plasma concentrations were expressed as the absorbance value  $A_{400}$ .

Plasma alkali-soluble melanin (SpASM, comprising phaeomelanin and eumelanin) was measured by the above spectrophotometric analysis, but samples were solubilized using 8M urea–1M sodium hydroxide instead of phosphate buffer. Plasma concentrations were expressed as the value for  $A_{400}$ .

Plasma total melanin (SpTM) also was measured by spectrophotometric analysis (Ozeki et al., 1995, 1996a). An aliquot of 100  $\mu$ L of plasma was mixed with 900  $\mu$ L of soluene 350 (Packard, Meriden, CT, USA) and then the mixture was heated in a boiling water bath for 45 min. After cooling, the absorbance of the boiled mixture was measured at both 500 nm ( $A_{500}$ ) and 650 nm ( $A_{650}$ ) and the SpTM value was taken as the  $A_{500}$  reading. The ratio of the values for  $A_{650} : A_{500}$  was taken to represent the ratio of eumelanin : total melanin (SpEM : SpTM) in the plasma sample (Ozeki et al., 1996b).

For all plasma samples, duplicate analyses were made.

## 7 Bioinformatics analyses

Functional domain prediction was effected using an online server (<http://www.bioinfotlo.org/domac.html>). Protein motif prediction was conducted using the PROSITE motif search tool (<http://www.cbs.dtu.dk/services/NetNGlyc/>). The likelihood of the non-synonymous coding single nucleotide polymorphisms causing a putative functional impact on the protein was predicted using the Protein Variation Effect Analyzer (PROVEAN) software volume 1.1 ([http://provean.jcvi.org/seq\\_submit.php](http://provean.jcvi.org/seq_submit.php)).

## 8 Genetic diversity and statistical analyses

Genotypic and allelic frequencies were calculated by direct count. Differences in the distribution of genotypes and alleles between the three groups of sheep and deviation from the Hardy–Weinberg equilibrium were assessed using the  $\chi^2$  test.

Population genetic diversity parameters, including heterozygosity ( $H_e$ ), homozygosity ( $H_o$ ), effective allele numbers ( $N_e$ ) and polymorphism content (PIC), were calculated as described by Nei and Li (1979).

The association between genotype and melanin-related traits was analyzed using the general linear model (GLM) procedure (SAS Institute Inc., Cary, NC, USA) according to the following relationship:

$$Y_{ij} = \mu + P_i + G_j + e_{ij},$$

where  $Y_{ij}$  represents the observation of the melanin-related traits,  $\mu$  is the least squares mean,  $P_i$  is the effect of its pop-

ulation ( $i$  being either the NPBB, NPN or RM sheep),  $G_j$  is the effect of the particular genotype and  $e_{ij}$  is the random residual.

Values for all traits have been presented as means  $\pm$  SE (standard errors) of the means.

Statistical significance was determined using the Duncan's new multiple range test and a  $P$  value of 0.05 was taken to denote statistical significance.

## 9 Results

### 9.1 Sequence characteristics of *TYRP1* and *TYRP1* exons

The 4,956bp genomic sequence of the *TYRP1* gene of NPBB sheep was assembled and deposited on the GenBank database with accession number EU760771. Eight exons and their partial flanking regions were amplified. Using the GT-AG rule for donor and acceptor sites in the splice sites between exon–intron boundaries (Frandsen et al., 2008) and comparing with sheep *TYRP1* gene coding regions (EF102110), the lengths of exons 1–8 for NPBB sheep were respectively 19, 385, 323, 295, 168, 180, 147 and 206 bp. Exon 1 was an un-coding exon so the remaining seven coding exons consisted of an open reading frame comprising 1,614bp (GenBank accession number EU760770) encoding a protein of 537 amino acids with a predicted molecular mass of 60 623 Da ( $pI$  6.48).

Based on the bioinformatics analysis, the signal peptide was identified between amino acids 1 and 23 at the N-terminus. Five N-linked glycosylation sites were retrieved. Sheep *TYRP1* has an epidermal growth factor (EGF-like) domain (amino acids 98–1090) and two histidine-rich metal ion-binding sites at amino acids 192–224 and 377–404). A total of 15 cysteine residues were conserved among the tyrosinase gene family (*TYRP1*, *TRYP2* and *TYRP*; see Fig. 1).

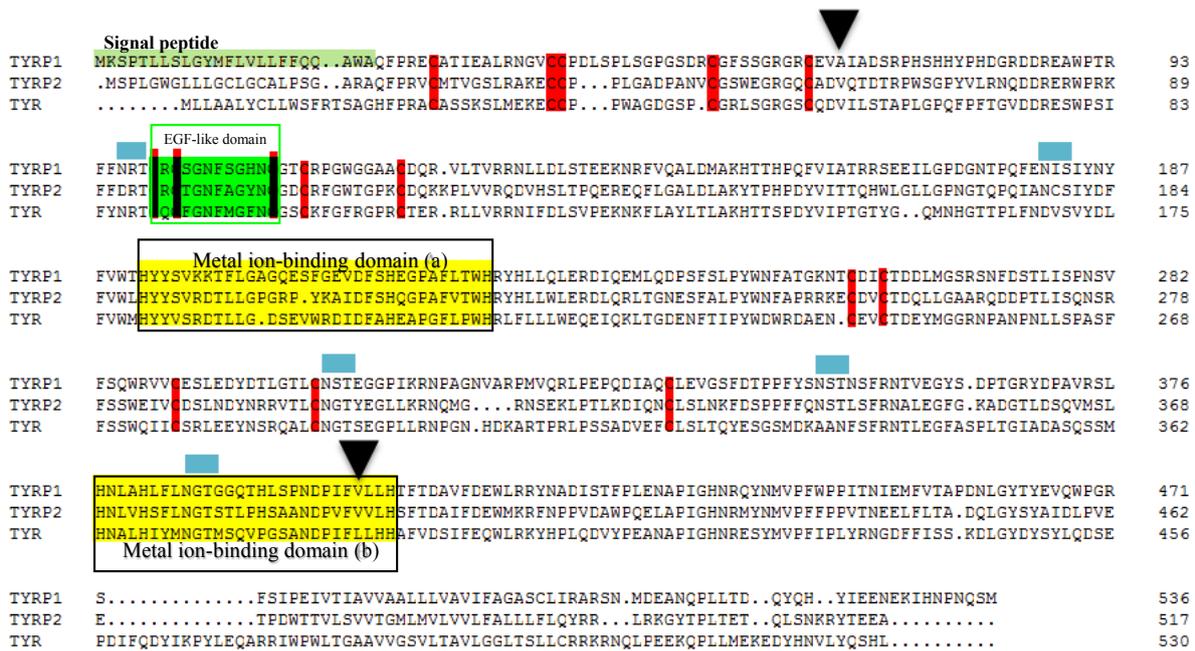

### 9.2 Identification and distribution of *TYRP1* gene polymorphisms

The following 12 SNPs were identified by sequencing bi-directionally.

g.602T > G (intron 1, c.-57T > G)	g.748T > C (exon 2, c.90T > C)
g.861C > T (exon 2, c.203C > T)	g.1601T > G (intron 3, c.708 + 15T > G)
g.1720A > G (intron 3, c.708 + 134A > G)	g.1742G > A (intron 3, c.708 + 156G > A)
g.2066G > T (intron 3, c.709-206G > T)	g.3011T > C (exon 5, c.1038T > C)
g.A3449T (intron 5, c.1082-15AA > T)	g.3489T > C (exon 6, c.1107T > C)
g.3584T > C (exon 6, c.1202T > C)	g.4760C > A (exon 8, c.1470C > A)*

\* location corresponded to EU760771

Six of the above sites in genomic location had corresponding locations in coding regions (EF102110). The sites and their

**Figure 1.** Alignment of the sequences for the tyrosinase family of enzymes TYRP1, TYRP2 and TYR. A signal sequence at the N-terminus (residues 1–23) is shaded. The epidermal growth factor (EGF-like) domain and metal ion-binding domains are boxed. The conserved cysteine is marked by a reddish bar. The N-linked glycosylation sites are revealed by the blue boxes. The triangle indicates the non-synonymous mutation. GenBank accession numbers are EU760772, EU760771 and EU760769 for the TYR, TYRP1 and TYRP2, respectively.

corresponding locations were as follows.

- g.748T > C      corresponded to c.90T > C
- g.861C > T      corresponded to c.203C > T
- g.3011T > C     corresponded to c.1038T > C
- g.3489T > C     corresponded to c.1107T > C
- g.3584T > C     corresponded to c.1107T > C
- g.4760C > A     corresponded to c.1202T > C

The sites c.90T > C, c.1038T > C, c.1107C > T and c.1407C > A were not changed for encoded amino acids, but the SNPs c.203C > T and c.1202T > C belonged to non-synonymous mutations and led to changes in the amino acids from alanine to valine at position 68 (p.A68V) and valine to alanine at position 401 (p.V401A). Furthermore, the variant p.V401A was clustered into the metal ion-binding domain B. The PROVEAN scores for the mutations p.A68V and p.V401A were 3.234 and -2.624, respectively, raising the possibility that the variation of c.1202T > C (p.A68V) may be deleterious (cutoff = -2.5).

### 9.3 Genotype and allele frequencies of the *TYRP1* gene

The genotypes and allelic frequencies of the two coding SNPs of the *TYRP1* gene (c.203C > T and c.1202T > C) in the three groups of sheep are shown in Fig. 2. All groups of sheep exhibited similar genotypes. The  $\chi^2$  test was used to show that the distributions of genotypes for the *TYRP1* gene

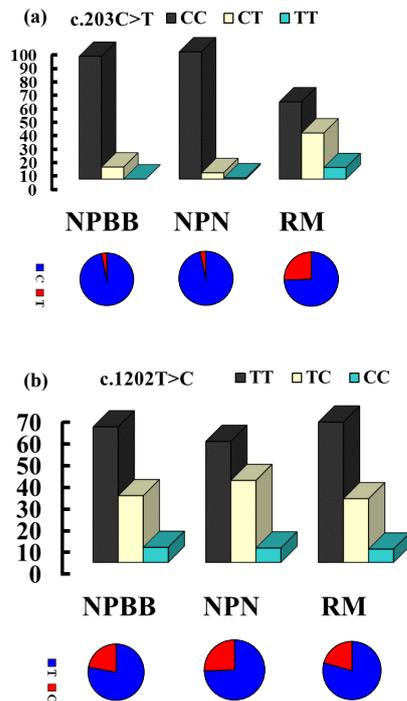

were in agreement with the Hardy–Weinberg equilibrium in all three groups of sheep. There were marked differences in the distribution of the genotypes between the RM sheep and both groups of sheep from Nanping ( NPBB and NPN sheep). Differences for the NPBB and NPN sheep for the SNPs investigated were not significant.

Values for gene homozygosity ( $H_o$ ), gene heterozygosity ( $H_e$ ), effective allele numbers ( $N_e$ ) and polymorphism content (PIC) for the above SNPs of the *TYRP1* gene are shown in Fig. 3. The values for  $H_o$ ,  $H_e$ ,  $N_e$  and PIC for the three groups of sheep were similar. On the basis that a value for PIC between < 0.25 corresponds to a low level of polymorphism and a value between 0.25 and 0.50 corresponds to a medium level of polymorphism (Zhao et al., 2009), the levels of polymorphism for the *TYRP1* gene in all three groups of sheep fell in the low to medium range.

### 10 Association analysis of the *TRYP1* genotype with melanin-related traits and coat color

The activity of tyrosinase in the plasma of the NPBB sheep was significantly higher ( $P < 0.01$ ) than in the plasma of the NPN sheep, which had a significantly higher ( $P < 0.01$ ) activity of plasma tyrosinase than for the RM sheep (Fig. 4a).

Values of SpPM, SpASM and SpTM, as well as the ratio of SpEM:SpTM, were consistently and significantly ( $P < 0.01$ ) higher for the NPBB than RM sheep. Although

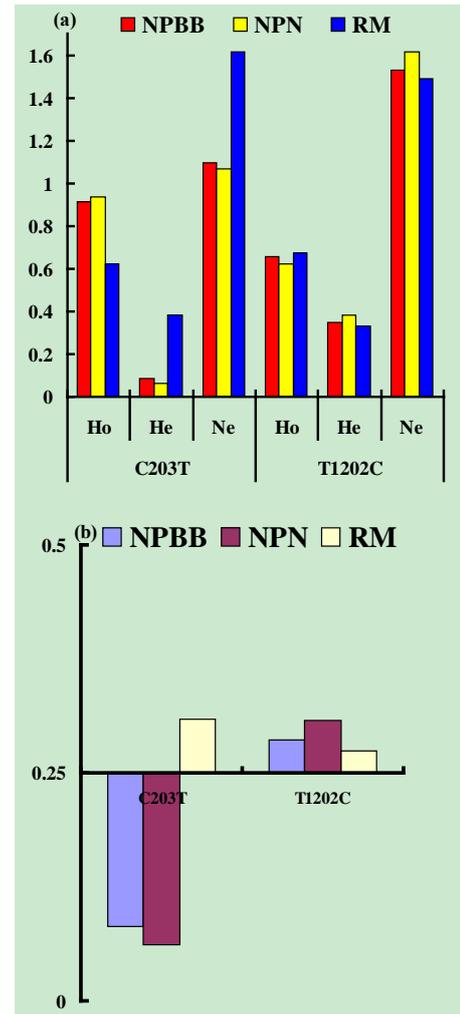

**Figure 2.** The genotype and gene frequencies of the SNPs c.203C > T (a) and c.1202T > C (b) from the *TYRP1* gene in Nanping black-boned (NPBB), Nanping normal (NPN) and Romney Marsh (RM) sheep.

the values of SpPM were similar for NPBB and NPN sheep, the concentrations of SpASM, SpTM and the ratio of SpEM : SpTM were significantly lower ( $P < 0.01$ ) for the NPN than NPBB sheep. Values of SpTM were similar for the NPN and RM sheep but values of SpTM, SpASM and the ratio of SpEM : SpTM were significantly lower ( $P < 0.01$ ) for the RM than NPN sheep (Fig. 4b).

Associations between genotype and melanin-related traits for the SNPs c.203C > T and c.1202T > C are presented in Table 2. In the case of SNP c.203C > T there were no significant ( $P > 0.05$ ) associations between genotype and melanin-related traits. When the data for all sheep were pooled, in the case of SNP c.203C > T, sheep with the CC genotype showed significantly higher ( $P < 0.05$ ) values for tyrosinase activity, SpPM, SpTM and the ratio of SpEM : SpTM than sheep with the CT and TT genotypes for which similar values were measured for all traits. In the case of the SNP c.1202T > C, no significant associations were measured for each of the genotypes and melanin-related traits.

In the case of coat color, polymorphism of the site c.203C > T had a significant effect ( $P < 0.01$ ) on coat color in the NPN group of sheep. No significant effects of polymorphism on coat color was measured for SNP 1202T > C even though the majority of the NPBB sheep of each of the three genotypes had black or brown coats (Table 3).

**Figure 3.** Genetic diversity parameters at the SNPs c.203C > T and c.1202T > C from the *TYRP1* gene in Nanping black-boned (NPBB), Nanping normal (NPN) and Romney Marsh (RM) sheep. (a) Ho: gene homozygosity; He: gene heterozygosity; Ne: effective allele numbers. (b) PIC: polymorphism information content.

## 11 Discussion

Tyrosinase is a rate-limiting enzyme for the synthesis of melanin within the enzymatic cascade (Cone et al., 1996; Hall and Orlow, 2005). When the activity of tyrosinase is low, the production of cysteinyl-DOPA occurs without the synthesis of melanin. As the activity of tyrosinase increases cysteinyl-DOPA is oxidized to form phaeomelanin and when the activity of tyrosinase is high the enzymatic cascade tends to result in the production of more eumelanin (Ito et al., 2000). Both TYRP1 and TYRP2 stabilize and improve the activity of tyrosinase.

In the present study, the NPBB sheep had a significantly higher ( $P < 0.01$ ) activity of tyrosinase in plasma than the NPN and RM sheep. The NPBB sheep also had significantly

**Table 2.** Association analysis of the *TYRP1* gene with black traits (least squares mean value  $\pm$ 1 SE; SE indicates the standard errors of the means) in the three flocks of sheep and all sheep sampled.

<sup>a,b,c</sup> Values in the same column indicate that either the three populations or all sheep with different superscripts differ ( $p < 0.05$ ).

more ( $P < 0.01$ ) plasma pheomelanin, total melanin and alkali-soluble melanin as well as more eumelanin (calculated as SpEM / SpTM  $\times$  SpTM) than the NPN and RM sheep. The NPBB sheep revealed specific black traits differing from normal sheep and other mammals, confirming the earlier report of a study with fewer NPBB sheep (Deng et al., 2006).

The genomic sequence of 4956 bp, covering eight entire exons and partial flanking regions, of the gene for *TYRP1* of the NPBB sheep was retrieved using eight pairs of primers. It was found that there were 12 polymorphic sites including 4 synonymous and 2 non-synonymous mutations (p.A68V and p.V401A) in exonic regions and 6 other sites in intronic regions. In a similar study of

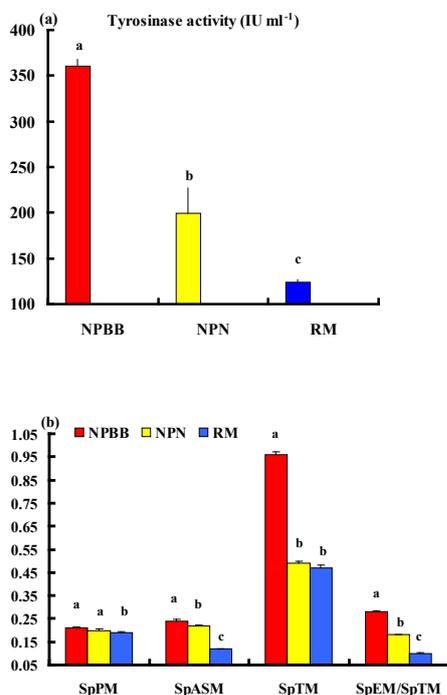

pigmentation with Soay sheep, six coding SNPs (including c.90C > T, c.869G > T, c.1107C > T, c.1339A > G, c.1442C > T and c.1470A > C) were identified (16). Three SNPs (viz. c.90C > T, c.1107C > T and c.1479A > C) were shared between the sheep investigated in this study (Nanping indigenous and RM sheep) and the Soay sheep.

As shown in Fig. 1, the deduced protein TYRP1 was characterized by classical motifs including the signal peptide, an EGF-like domain, conserved cysteine sites, N-linked glycosylation sites and metal ion-binding domains A and B. These motifs are consistent with the sheep family of tyrosinase enzymes having all the important features necessary for folding, maturation, glycosylation and sorting, like active en-

**Table 3.** The *TYRP1* genotype with coat color distribution in the three groups of sheep.

**Figure 4.** Plasma tyrosinase activity (a) and concentrations of phaeomelanin (SpPM), alkali-soluble melanin (SpASM) and total melanin (SpTM) in the plasma as well as the ratio of plasma eumelanin : total melanin (SpEM : SpTM) for the Nanping black-boned, Nanping normal and Romney Marsh (RM) sheep (b). Values presented are means and values shown with different letters (a–c) differ significantly ( $P < 0.01$ ).

zymes in the melanosome (Guibert et al., 2004). It is of interest that the variant p.401V > A, which appears to have a deleterious effect on the function of TYRP1, was located at the metal ion-binding domain B.

The results for the bi-PASA analyses for the pooled data for all three groups of sheep in the present study (see Table 2) were interpreted as evidence that for the mutation c.203C > T of the *TYRP1* gene, sheep with the CC, compared to those with CT and TT, genotype had significantly higher ( $P < 0.05$ ) tyrosinase activity in the plasma and plasma contents of alkali-soluble and total melanin as well as ratio of plasma eumelanin : total melanin. However, these differences were not detected within the separate groups of sheep. The great majority of the sheep from the NPBB and NPN groups with CC and CT genotypes displaying the mutation c.203C > T had black, brown or mixed-colored coats. In contrast, within the group of RM sheep all the sheep exhibited white coats. In the cases of sheep displaying the c.1202T > C mutation, there were no significant associations between plasma tyrosinase and melanin for the three genotypes (Table 2). In these groups of sheep the majority of NPBB and NPN sheep with the TT and TC genotypes had black, brown or mixed-colored coats, whereas all the RM sheep had white coats (Table 3). Overall, these observations are considered to be consistent with the previous report that plasma tyrosinase activity is higher in sheep with black skin than in those with white skin (Pomerantz and Ances, 1975; Iwata et al., 1990). In Soay sheep the coat is either dark brown or a light tawny color. A non-synonymous mutation (c.869G > T; p.290C > F) of the *TYRP1* gene has been reported to be responsible for the light phenotype (Gratten et

al., 2007). This site mutation has also been reported to have an association with partial dominance for body size in Soay sheep (Gratten et al., 2008).

Recently the gene expression profiles in sheep with either white or black coat colors were compared using a transcriptome sequencing technique. A total of 2235 known genes and 845 novel genes were found to be expressed in sheep with black compared to white skin. The *TYRP1* gene was shown to have the highest level of differential expression. There were 13 coat color genes, including the tyrosinase gene family, expressed higher in sheep with black compared to white skin (Fan et al., 2013). Recently in a study with NPBB and NPN sheep, no differences for the mRNA expression levels were found for the *TYRP1* gene in different organs and tissues (Deng WD, unpublished data). It appears that coat color in the sheep is influenced by several genes, pathways or networks (Bellei et al., 2011). Indeed, it is known that more than 150 genes and 300 genetic loci (Norris and Whan, 2008; Hofreiter and Schöneberg, 2010; Cieslak et al., 2011; Aydin et al., 2012; Li et al., 2014) and environmental factors affect the pigmentation of the integument, including coat color, in animals. Given the latter, coat color in NPBB is likely to be affected by more than the variants of the *TYRP1* gene.

It is concluded that while it is clear that NPBB sheep have higher contents of melanin and related pigments in tissues and organs than NPN and RM sheep, these traits were not solely due to variations in the coding SNPs of the *TYRP1* gene c.203C > T and c.1202T > C. Further studies using whole genome re-sequencing technology should be undertaken to determine the genes responsible for the black traits in the novel and economically important NPBB sheep.

**Data availability.** Data are available upon reasonable request from the corresponding author.

**Competing interests.** The authors declare that they have no conflict of interest.

**Acknowledgements.** This work was supported by grants from the National Nature Science Foundation of China (31660634) and Yunnan Province (2016FA007). The authors appreciate the help of the staff from the Animal Science and Veterinary Bureau in Nanping and Jiachuan counties and local farmers Fuhai Yang and Sinanduojie during sample collection.
